SYNTHESIS OF METALLIC COMPOSITE BASED ON IRON FRAME AND SiC NANOSTRUCTURES AND ITS STRENGTH PROPERTIES

St Petersburg State University, Universitetskaya emb. 7/9, St Petersburg 199034, Russia

*e-mail: b.semenov@spbu.ru

Abstract. The article discusses a new approach to the synthesis of metallic composite materials based on nanostructuring of a metal frame (on the example of iron) by SiC nanostructures (10-50 nm). Optimal conditions are established for the nano-SiC coating on the porous Fe surface during sequential chemisorption of Cl₂Si(CH₃)₂ and CH₄ molecules from the gas phase. The resulting composite possesses enhanced strength in comparison with the best steel samples although the residual porosity (up to 5%) of Fe matrix is still preserved after pressing.

Keywords: composite, metallic framework, iron, disperse phase, SiC, ultimate strength

1. Introduction
One of the crucial tasks of modern materials science is the development of new composites with improved functional properties [1]. The importance of an interdisciplinary approach to this task should be noted [2-4]. The structural organization of matter is one of the key problems of natural science. This is because the questions of the matter organization at different levels are studied by physics, mechanics, chemistry, and biology. Establishing physical and chemical parameters that control the properties of artificially ordered nanostructures materials based on them is one of the most important areas of world research. From the physical mesomechanics point of view, chemical nanostructuring of materials leads to new objects with multi-level organization, which is necessary for a more correct approach to the study (experimental and theoretical) of structural transformation at the nanoscale level [2-6].

Iron- or aluminum-based composites are important materials for a wide range of structural applications. An enhancement of the mechanical properties of iron- or aluminum-based composites can be realized by creating a nanoscale structure with high uniformity and well-formed intergranular boundaries [2,7].

Known metal composites fabrication techniques [1,2] cannot give a uniform distribution of the dispersed phase in the bulk matrix. The lack of uniform distribution prevents the achievement of the maximal mechanical properties of the composite [6].

We have developed a new approach to the synthesis of composites based on the processes of three-dimensional nanostructuring (reinforcement) of the matrix frame with a dispersed nanophase [8-11].

Metal matrix nanostructuring involves the distribution of nano-carbide in the bulk porous matrix. The product is a composite material comprising an iron metallic frame reinforced (permeated) with silicon carbide (SiC)-based nanostructures with improved strength.

The purpose of this work was to establish the conditions for obtaining SiC nanolayers on the nanodispersed porous Fe powder surface. In fact, the composite formation process includes 3 main stages:

1. Fabrication of Fe matrix with a pre-defined porosity;
2. Surface modification of prepared porous Fe matrix with SiC (10-50 nm) nanostructures.
3. Pressing and sintering to produce a massive (non-porous) Fe/SiC nanocomposite.

2. Materials and Methods

**Chemicals.** The chemicals were obtained from commercial suppliers: SiCl₄ (99.6%), (Alfa Aesar), CCl₄, Cl₂Si(CH₃)₂, (Sigma-Aldrich), FeCl₂·4H₂O, NaOH (Merck), and CH₄ (gaseous) (Lengaz).

**Methods.** The powder phases were identified by powder XRD using Bruker D2 Phaser diffractometer with a cobalt anode.

The morphology of samples was studied with the scanning electron microscope (Zeiss Merlin) operated at 10–15 kV in In-lens, SE2, and EDS modes. The magnifications from 300 up to 600 000 (spatial resolution 1 nm) were used.

The Mössbauer spectra were recorded at the constant acceleration in combination with the use of a multichannel Nuclear Data Instruments ND 60 analyzer. In our work, we used a $^{57}$Co radiation source that decays to $^{57}$Fe.

Specific surface ($S_{sp}$) of the samples were determined using BET model of nitrogen adsorption. From specific surface values $S_{sp}$, the average size of powder particles can be evaluated according to the equation $d_{av} = 6/(\rho S)$, where $\rho$ is substance density.

The ultimate strength ($\sigma_b$) was determined on the AG-50kNXD desktop testing machine (Shimadzu) at the Resource Center for innovative composite materials technologies of St. Petersburg State University.

**Iron nanoparticles fabrication.** As it is known, with a decrease in grain size, the strength increases while maintaining plasticity. The effect of low-temperature and high-speed superplasticity is manifested, and physical properties changes are observed.

In order to obtain Fe NPs of high dispersion, it is necessary to use the precursors that could be reduced at a possibly lower temperature [1]. So, we selected the way via amorphous iron oxide-hydroxide FeOOH as intermediate.

FeOOH was synthesized by precipitation from FeSO₄·7H₂O using NaOH in distilled water.

Final precipitate was washed with distilled water and dried at 120°C for 5 h.

Fe nanopowders were obtained by subsequent FeOOH (1 g) reduction in a quartz tube furnace with nichrome heaters at 400°C for 90 min. Hydrogen (≥99.99% pure) was used as the reductant. The rate of the H₂ supply was 2–5·10⁻⁶ m³/s. As a result, we produced Fe nanoparticles denoted as [Fe]ₓH.

**Iron nanoparticles compaction.** [Fe]ₓH (particle size of 60 nm) was uniaxially compacted in a cylindrical mold (internal diameter 15 mm; the height of the compact 5-7 mm).

Optimized pressing conditions were suggested after pre-experiments: powder weight 9g, height of the resulting sample $h = 4.96$ mm, diameter = 15 mm, $\rho = 4.60$ g/ml. The pressure of 200 MPa loaded during 60 s, maintained for 180 s, then unloaded during 30 s.

The compacts' density was determined by hydrostatic weighing with an accuracy of 2 %.
These conditions provide Fe samples with 20-30% residual porosity. This is proved to be sufficient for further surface chemical reactions.

**ALD deposition of SiC.** SiC dispersed phase on Fe was produced by ALD [12-18] in a flow-type reactor. The ALD technique is based on alternating chemical reactions of low molecular weight reagents on the surface. As a result of each reaction cycle, new carbide unit was added chemically bonded to the support. Depending on the number of such cycles, layers of the various thickness are synthesized. The chemical composition of the samples was determined by photocolorimetry for silicon and chemical analysis for carbon, based on burning the sample in oxygen and gas chromatographic determination of carbon in CO and CO₂.

Stream of dry helium was used both to provide an inert atmosphere and to assist the removal of gaseous by-products from the reactor. The synthesis temperature was 200-500°C.

It's important that when storing, [Fe]₆H is covered by the surface oxide layer of varying thickness. The composition of the oxide layer (usually 3-5 nm thick) is not stable and varies depending on storage conditions and other factors. So, it was necessary to purify Fe surface from the oxide layer before deposition. For this purpose, we used surface standardization. According to the developed approach, at this stage, metallic Fe particles were chlorinated to form \( \text{Fe-Cl} \) groups on the surface:

\[
[\text{Fe}]_6\text{H} + \text{CCl}_4 \rightarrow [\text{Fe}]_6\text{Cl} + \text{HCl} \uparrow.
\]

In this way we cleaned the surface from undesired functional groups.

Next, Fe powders (~80 nm) were pressed together with SiC nanostructures and sintered to produce a non-porous composite. Fe/SiC powders uniaxially compacted in a cylindrical mold (internal diameter of 15 mm, the height of the compacts 5-7 mm) at a pressure of up to 500 MPa, holding under pressure for 180 seconds.

Finally, Fe/SiC samples were sintered in a tube furnace. To achieve the lowest porosity, composites were sintered in H₂ atmosphere at 950°C for 2 hours with preheating the press from 700 to 950°C for 1 h.

### 3. Results and Discussion

TEM images for FeOOH particles are shown in Fig. 1. FeOOH particles showed the presence of aggregates with a length of \( \leq 50 \) nm. \( S_{sp} \) for FeOOH is found to be 198 m²/g from the nitrogen sorption experiment.

![TEM image of FeOOH particles](image)

**Fig. 1.** Electronic microphotographs of FeOOH samples

Comparing the size of iron nanoparticles for FeOOH samples reduced at different temperatures, it follows that an increase in the reduction temperature of FeOOH samples from 400 to 550°C leads to an increase in the size of metallic iron particles.
The effect of reduction conditions on the phase composition, structure, and dispersion of resulting Fe powder was studied. Analysis of Fe powders by Mössbauer spectroscopy after reduction for 90 minutes at a temperature of 400°C and after reduction for 60 minutes in the temperature range of 450-550°C, showed that the samples contain only $\alpha$-Fe (Fig. 2).

**Fig. 2.** Mössbauer spectrum of Fe sample obtained from FeOOH dried at 120°C and reduced by H$_2$ at 400°C

The experimental specific surface areas and the calculated average sizes of dispersed Fe particles are listed in Table 1. An increase of reduction temperature from 400 to 550°C leads to a decrease in $S_{sp}$ of metallic Fe from 8.4 to 2 m$^2$/g. Further, FeOOH reduction at 400°C for 90 minutes was used for the experiments.

To create a nanostructured material, it is necessary at the first stage to obtain a metal matrix with a certain porosity.

The pressure varied from 50 MPa to 300 MPa. The pressing time ranged from 30 seconds to tens of minutes. The loading and unloading time varied from seconds to minutes.
The following mode was selected to get a Fe matrix with residual porosity 20-30%. For Fe NPs, applying a pressure of 200 MPa for 60 seconds, holding under pressure for 180 seconds, unloading for 30 seconds, powder weight – 9 g. Residual porosity is required for surface chemical reactions on the pore surface of Fe NPs.

**The synthesis of SiC nanostructures on the porous iron matrix surface.** SiC nanostructures on the porous Fe matrix surface were ALD-synthesized based on a series of successive surface reactions with functional groups on the surface. An important feature of ALD nanolayers is the absence of nucleation under certain synthetic conditions, which allows tuning the functional properties of the product more finely.

The synthesis included the following sequence of operations:

1. Porous Fe particles (1 g) were exposed to CCl₄ vapors at 350°C to remove the oxide layer (reaction 1).

2. Chlorinated samples underwent direct treatment by vapors of silicon-containing CH₃SiH for attaching silicon-carbon groups to the Fe particles surface (reaction 3).

3. Alternatively, the chlorinated sample was first converted to methylated one by methane treatment at 500°C (reaction 2). After that, the methylated sample reacted with Cl₂Si(CH₃)₂ (reaction 4).

\[
[\text{Fe}]\alpha\text{H} + \text{CCl}₄ \rightarrow [\text{Fe}]\alpha\text{Cl} + \text{HCl}↑, \quad (1)
\]

\[
[\text{Fe}]\alpha\text{Cl} + \text{CH}_4 \rightarrow [\text{Fe}]\alpha\text{CH}_3 + \text{HCl}↑, \quad (2)
\]

\[
[\text{Fe}]\alpha\text{Cl} + \text{CH}_3\text{SiH} \rightarrow [\text{Fe}]\alpha\text{CH}_2\text{SiH} + \text{HCl}↑, \quad (3)
\]

\[
[\text{Fe}]\alpha\text{CH}_3 + \text{Cl}_2\text{Si(CH}_3)_2 \rightarrow [\text{Fe}]\alpha\text{HC} = \text{Si(CH}_3)_2 + 2\text{HCl}↑, \quad (4)
\]

\[
[\text{Fe}]\alpha\text{HC} = \text{Si(CH}_3)_2 + \text{Cl}_2\text{Si(CH}_3)_2 \rightarrow [\text{Fe}]\alpha\text{HC} = \text{Si(CH}_3)_2 + \text{HC} = \text{Si(CH}_3)_2 + 2\text{HCl}. \quad (5)
\]

Reaction (3) resulted in the substitution of Cl by silicon-carbon groups. Since methylsilane is thermally stable up to 400°C, this reaction was performed in the range of 300-400°C. However, in this range, the replacement of Cl with silicon-carbon groups was not effective enough – ca. 40% (according to the Cl content in the product).

At the same time, methylation (reaction 2) and subsequent reaction with Cl₂Si(CH₃)₂ is found to give almost 100% replacement.

Based on these results, we further used reaction (4). Chemical analysis of modified Fe suggested that the Si and Cl content reaches a maximum at 400°C. The amounts of reacting silicon and chlorine on the sample remain approximately constant, with the Cl/Si ratio 2.4–2.6. Above 450°C the silicon content significantly decreases. Further increase of SiC nanolayer thickness is performed using reaction (5).

The reaction product comprises the Fe particles surface with silicon-carbon tails HC=Si(CH₃)₂ covalently bound to surface –CH₃ groups.

As a result of this work, Fe/SiC samples with varied SiC content were synthesized (Table 3).

Figure 3 shows the XRD pattern of sample No. 6 (SiC content 25.5 wt. %) that confirms the presence of α-Fe and SiC peaks.
It is found that in the range of 700-800°C, SiC is in a partially amorphous state, while higher heating temperatures (900°C and more) leads to the formation of polycrystalline SiC. Based on XRD data, the average size of SiC crystallites after heating at 700-800°C is found to be ~2 nm, and at 900°C is ~6 nm.

Pressing and sintering of iron coated with hardening SiC nanostructures. Bulk nanocrystalline materials are of high interest because their structural and functional properties differ significantly from those of coarse-grained analogues [9,19].

Nanocrystalline materials are usually obtained by powder metallurgy, crystallization from an amorphous state, and severe plastic deformation. Features of nanocrystalline materials (grain size, a significant amount of interfaces, porosity, and other structural defects) depend on the preparation methods and have a significant impact on their properties.

The optimal conditions to achieve the best strength of non-porous compacts were analyzed, namely, the temperature and duration of sintering and pressing, intermediate temperature exposures, and the sintering medium (argon or hydrogen).

The pressure of 0.05 to 1.1 GPa was applied. A further increase in pressure does not lead to a significant increase in the compact density. At pressures of up to 0.5 GPa, the nanopowders compacted much less intensely than coarse particles. The loading time was varied from 1 to 23 minutes, the exposure duration under load ranged from 1 to 3 minutes, the duration of unloading was 2-4 minutes. The results of powder pressing show that loading for more than 15 minutes leads to the absence of cracks in the samples. Increasing the holding time under load from 1 to 3 minutes also leads to similar results.

To achieve the lowest porosity, compacts must be sintered in H$_2$ at 950°C for 2 hours with preheating of the press from 700 to 950°C for 1 h. This mode of sintering allowed to increase the density of the bulk sample (porosity is reduced to 5%). Sintering at a temperature above 1000°C did not improve the residual sample porosity.

Figure 4 depicts the nanowire formation on the $\alpha$-Fe NPs surface. A SiC nanolayer of a predetermined thickness is formed on the surface of $\alpha$-Fe nanoparticles. During the pressing and sintering stages, the pore walls of $\alpha$-Fe NPs with a SiC nanolayer move towards each other. As a result, the SiC nanolayers are combined, and finally, a SiC nanowire is formed that permeates the entire $\alpha$-Fe volume as a "frame within a frame" structure.
Fig. 4. Formation of the silicon carbide nanowires in the bulk nanocomposite on α-Fe: a) initial α-Fe with selected pore segment designated as B; b) pore segment on the walls of which the SiC nanolayer grows; c) SiC layers shift during pressing; d) merged SiC in the pore after compaction and sintering

Strength properties of metallic composites based on iron and silicon carbide strengthening nanomodifiers (Fe/SiC). The mechanical properties of nanomaterials depend significantly on the grain size. At the big grain sizes, an increase of the strength and hardness with decreasing grain size is due to the appearance of additional grain boundaries that are obstacles to dislocation motion. For small nanoscale grains, a strength increase is due to the low density of existing dislocations and the difficulty of new dislocations formation.

Strength data of Fe/SiC samples are presented in Fig. 5. For comparison, also the strength properties of the best grades of steel according to [20] are shown.

The ultimate strength of the obtained Fe/SiC composites is comparable to the properties of the best grades of steel, which contain a high percentage of alloying additives. Thus, it is evident that the formation of Fe/SiC composite using the surface structuring is a promising tool for obtaining new-generation composites.
4. Conclusion

The authors offered the structuration of an iron-based metal matrix with carbide nanolayers, which results the composite with a "frame within a frame" structure. A synthesis has been developed of SiC nanolayers on the porous surface of Fe matrix during sequential chemisorption of CH₄ and Cl₂Si(CH₃)₂ molecules from the gas phase.

The conditions are established for pressing and sintering a Fe bulk material with nano-silicon carbide to obtain a composite with minimal residual porosity and improved strength.

The ways of adjustment of metal materials strength using structuring the metal matrix (on the example of iron) with SiC are discussed.

The proposed approach can also be used to create analogous composites based on an...
aluminum frame with improved mechanical properties and is implemented via a nanosized material with a high degree of uniformity.
